

Real single neurons at the transient↔sustained extremes

GLM TF kernel = each cell's deconvolved response to a unit change in temporal frequency. TOP: SUSTAINED (stays elevated ~0.4–0.7 s) BOTTOM: TRANSIENT (a brief blip)
 Shaded band = 95% CI (trial bootstrap, 200×). Grey = the same cell's model-free FAST–SLOW pulse contrast + its 95% CI (background-cancelled): it tracks the kernel's shape but is far noisier — model-free corroboration, and why the deconvolving GLM is the better estimator.

NOTE — Illustrative exemplars, deliberately BEST-CASE: filtered to above-median kernel amplitude AND above-median TF selectivity AND >2000 spikes, then the 3 strongest of each extreme. They are the cleanest cells, NOT typical ones, and feed no statistic — the population support for the width axis is the all-cell ρ (width_continuum_summary / core_metrics_continuum), not this figure.
